

Understanding epilepsy one brain cell at a time

Rishun Sakai (Mentor) & Brian Kiernan (Mentee)

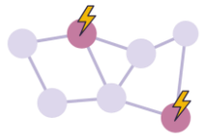
citizens of science

Background

Your brain is a network of billions of cells called neurons that pass messages using tiny electrical signals.

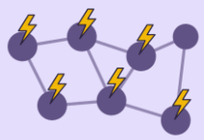
Epilepsy is a brain condition where seizures keep coming back. What a person notices depends on where it happens: jerking, changes in vision, confusion or losing awareness.

Injury, infection or a faulty gene can cause it, but often no cause is found, and medicines don't work well enough for about **1 in 3** people.



A healthy brain is like a busy crowd

Thousands of separate conversations at once. Cells "speak up" at different times, so you can think, move and remember.



A seizure is the whole crowd chanting

Cells suddenly fire together, out of control. With everyone shouting the same thing, normal brain work is drowned out.

Aim & Hypothesis

Aim: Find out whether epileptic brain cells handle incoming messages differently from healthy cells.

Hypothesis: In epilepsy, dendrites (the branches a neuron uses to "listen" to other cells) respond abnormally, helping seizures build up.

Method

1. Mouse model

Epilepsy-gene mice and healthy mice

2. Brain slice

Thinner than a coin, cells still alive

3. Find a neuron

Picked out under a microscope

4. Patch clamp

A glass tip finer than a hair seals on

5. Record

Its electrical signals show on screen

6. Compare

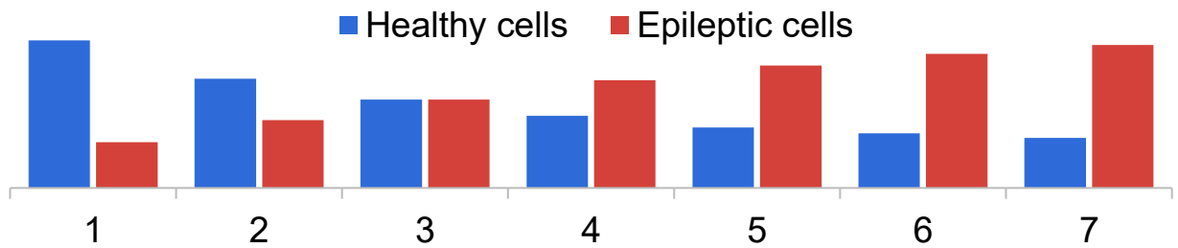
Healthy cells vs epileptic cells

Key Takeaways

Small changes in single brain cells may add up to seizures. Medicines act on cells, not on the whole network, so finding these changes gives new ideas for preventing and treating epilepsy.

Results

Response to the same signal, sent 7 times in a row



Healthy cells settled down with each repeat; epileptic cells kept getting stronger. (Illustration, not measured values.)

Many ways to study the brain

Each tool sees the brain at a different size and speed. Patch clamp (★) zooms in on single cells over milliseconds.
